Distance to a path crossing . . . 9
Has the return structure changed? . . . 10

7. Verdict 11

Purpose

This tool is the decision companion to the diagnostic report *Monthly pension returns analysis*, which serves as its technical appendix. That report establishes how each plan's returns are distributed and why the methods used below are the right ones; this tool applies them to your data and costs and turns them into the two decisions an investor actually faces:

1. **Which risk level** – and is a higher-risk plan anything more than a more-leveraged version of a lower-risk one?
2. **One provider or both** – is there diversification between PFA and Velliv, and could it plausibly beat the cost of splitting?

The returns reports' central caveat governs everything here: With about 13 years of data and fat tails, point estimates (means, Sharpe ratios, correlations) are noisy and regime-dependent. The tool is therefore built to expose *how robust* each conclusion is, not to emit a single "best" plan. Returns are monthly, 161 months (2012-07 to 2025-11). Sharpe ratios use the risk-free rate set in the inputs below. The comparison needs both providers, so it ends at the last month both have published: Velliv's index runs to 2025-11 and PFA's

returns to 2026-09. PFA's profiles appear by letter: A to D are today's Forsigtig, Lav, Middel and Høj, from lowest to highest risk.

Inputs

Every figure below is computed from your data and these settings. Change them in the YAML header at the top of this document, or pass them as render parameters.

Table 1: Current inputs. Sharpe ratios, certainty equivalents, fee break-evens and the stress simulation all read from these.

setting	value
Data folder	data/latest
Balance (kr)	1,000,000
Flat fee, Velliv (kr/yr)	984
Flat fee, PFA (kr/yr)	807
Proportional fee, Velliv	1.17%
Proportional fee, PFA	0.28%
Risk-free rate (annual)	2.0%
Risk aversion	2
Horizon (years)	20
Start date	full comparable window
Monitor window (months)	36
Assumed tail index	3.5
Assumed skew	0.7

The flat fees are each provider's fixed yearly charge, paid whatever the balance. The proportional fees scale with the balance and are mostly investment costs. Both providers publish returns after investment costs, so that part is already inside every return figure below. The flat fees come on top, and they drive the cost arithmetic of Section 4.

1. Current regime check

The reports' working model is a heavy-tailed, left-skewed return distribution. Before any mean-variance figure can be trusted, check whether the loaded data still look that way or have moved toward the Gaussian. A skewed-t fit answers it: A high tail index ν with a skew ξ near 1 is near-Gaussian; a low ν, or a ξ below 1, is heavy tails and left skew.

Table 2: Skewed-t fit per plan on the loaded data. A low tail index (heavy tails) or a skew below 1 (left skew) is the reports' regime; a high tail index with skew near 1 is near-Gaussian.

plan	tail index ν	ν SE	skew ξ	ξ SE
Velliv medium	3.4	1.1	0.71	0.08
Velliv high	3.5	1.2	0.72	0.08
PFA B	3.8	1.5	0.76	0.08
PFA D	4.1	1.5	0.73	0.08

Across these plans the median tail index is 3.7 and the median skew is 0.72. That is firmly heavy-tailed, the regime the reports assume, so the mean-variance figures here are body-of-distribution summaries and the tail caveats stand.

The test is deliberately asymmetric. A single extreme month can reveal a fat tail; no stretch of calm can prove its absence.

The latest month (2025-11) is within the fitted tails of every plan: No fresh tail signal, which on its own proves nothing. Calling the regime Gaussian instead needs far more data than a benign stretch provides. The tail parameters are not pinned down at 161 observations: By the reports' analysis, matching even 30 Gaussian observations for the *mean* takes on the order of 93 heavy-tailed observations, and the tail needs more still. Treat a quiet tail as unproven, not safe.

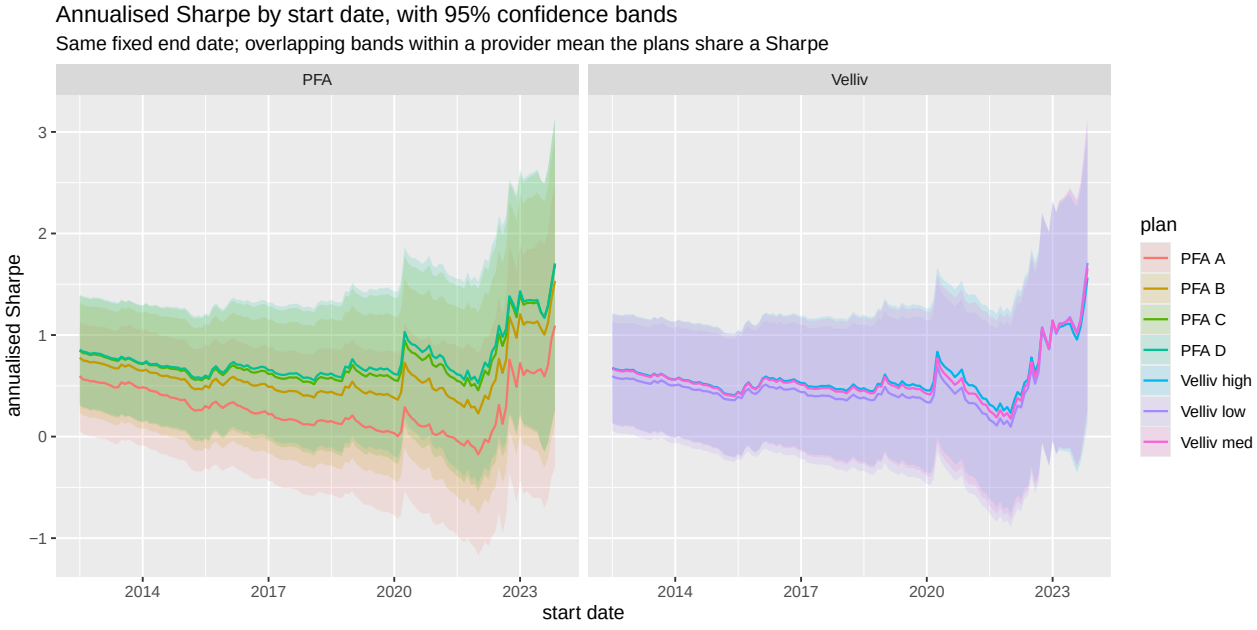

2. Within a provider: Which risk level?

A higher-risk plan is *pure leverage* of a lower-risk one when it has the same reward-to-risk (Sharpe) and the same distributional shape, only scaled. If so, choosing a risk level is a pure risk-appetite dial with no consequence for return-per-unit-risk. We test this with the Sharpe ratio of each plan and, crucially, its stability across sub-periods.

Table 3: Annualised Sharpe ratio by plan and start date.

	Velliv low	Velliv med	Velliv high	PFA A	PFA B	PFA C	PFA D
from 2012-07 (n=161)	0.59	0.67	0.68	0.60	0.78	0.85	0.86
from 2016-12 (n=108)	0.45	0.53	0.54	0.25	0.52	0.64	0.68
from 2021-05 (n=55)	0.23	0.32	0.38	0.00	0.38	0.59	0.66

The table samples three start dates. The plot below sweeps every start date that leaves at least two years of data to the same fixed end, with 95% confidence bands. Look for whether a provider's plans have overlapping bands: Where they do, the plans cannot be told apart on reward-per-risk.

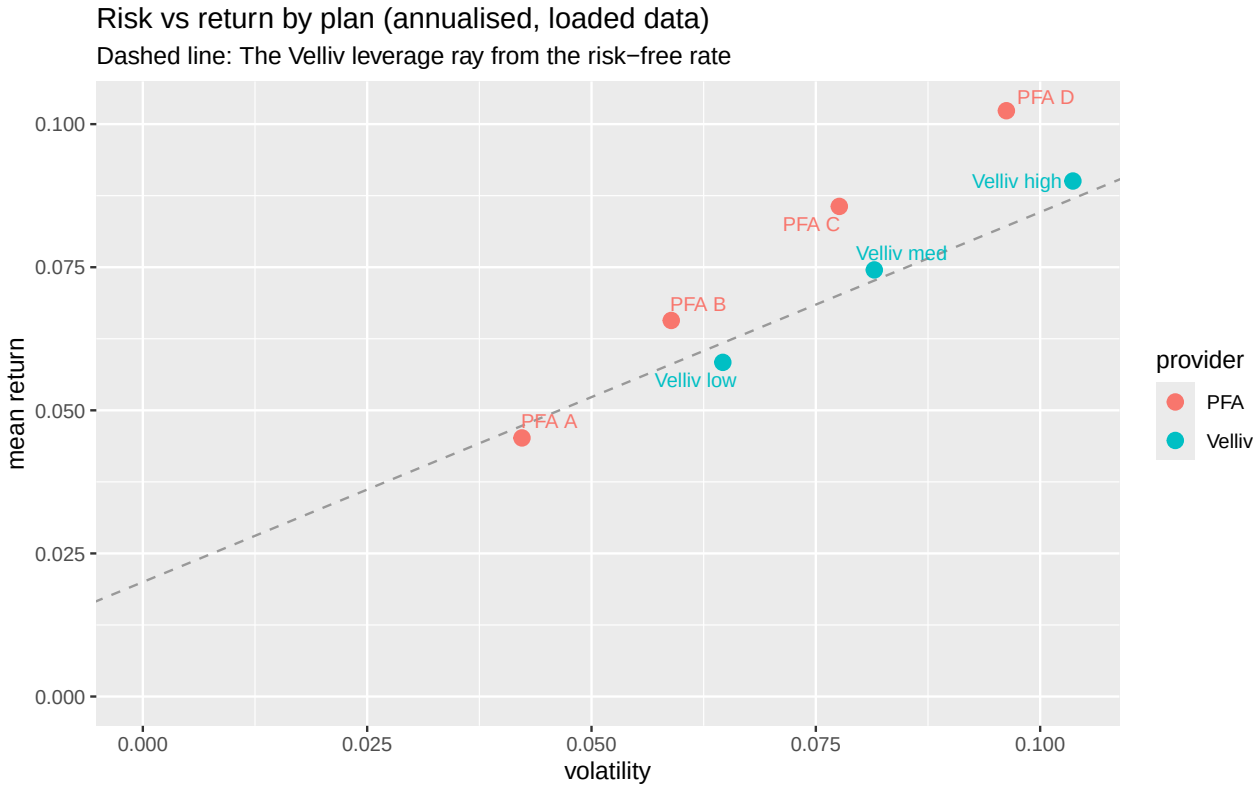

Velliv. The three plans' Sharpe ratios (around 0.6) span 0.08 against a sampling error of about 0.28. That spread is within the noise, so on this data Velliv behaves as a leverage ray. Choosing a Velliv risk level is then a pure risk-appetite decision, with nothing to optimise.

PFA. The four profiles' Sharpe ratios span 0.26 against a sampling error of about 0.28, so the menu is, within the noise, also a single ray. The highest-Sharpe profile is PFA D from every start date in the table.

But the spread is within the noise, so no best-Sharpe profile is reliably identifiable, and you should not pay, in added risk or in fees, to chase one.

The same test reads off the risk-return map. Each plan sits at its annualised volatility and mean return; plans on one line from the risk-free rate share a Sharpe ratio, and a plan off that line differs in reward-per-risk. Look for whether each provider's plans line up.

The derivation of the ray and its sampling error is in the Sharpe ratio section of the diagnostic report.

3. Across providers: Is there diversification?

Table 4: Correlation matrix of monthly returns across all plans.

	Velliv low	Velliv med	Velliv high	PFA A	PFA B	PFA C	PFA D
Velliv low	1.000	0.994	0.985	0.925	0.966	0.963	0.955
Velliv med	0.994	1.000	0.997	0.905	0.961	0.966	0.964
Velliv high	0.985	0.997	1.000	0.882	0.952	0.966	0.967
PFA A	0.925	0.905	0.882	1.000	0.969	0.927	0.898
PFA B	0.966	0.961	0.952	0.969	1.000	0.991	0.978
PFA C	0.963	0.966	0.966	0.927	0.991	1.000	0.996
PFA D	0.955	0.964	0.967	0.898	0.978	0.996	1.000

The lowest pairwise correlation is 0.88. Every pair moves closely together. The least-correlated plans are **PFA A** and **Velliv high**. For why the plans co-move, see the Path crossing section of the diagnostic report.

Table 5: 50/50 cross-provider mixes: Correlation and volatility reduction vs the weighted-average volatility.

	correlation	vol reduction
PFA A + Velliv high	0.882	2.5%
Velliv low + PFA D	0.955	1.1%
Velliv high + PFA D	0.967	0.8%
Velliv med + PFA B	0.961	1.0%

The largest risk reduction among these cross-provider mixes is **PFA A + Velliv high**, at about 2.5% of volatility. That is small, a few percent, not a step change: Cross-provider diversification does something, but little, in mean-variance terms. The reduction comes from pairing the least-correlated plans; the composition behind those correlations is in the Path crossing section of the diagnostic report.

The diversification that *does* work is within a provider

Splitting across providers pairs equity with equity. The diversification that actually reduces risk is across *asset classes* – bonds with equity – and it lives inside a single provider, harvested simply by choosing a risk level. PFA's profiles are fixed blends of two building-block funds, which can be backed out of the returns: The equity fund is $H = D$ and the bond-like fund is $L = (4A - D)/3$. Both are exact for simple returns, since A holds a quarter in the equity fund and D all of it, and neither weight changed in PFA's 2025 restructuring. Comparing the two kinds of 50/50 blend:

Table 6: Volatility reduction from a 50/50 blend: Within a provider (across asset classes) vs across providers (same risk level).

blend	correlation	vol. reduction
Within PFA: Mid-risk plan	0.59	8%
Across providers: Velliv-high + PFA-high (same risk level)	0.97	1%

The within-provider blend correlates about 0.6 and cuts volatility several times more than the cross-provider split. A single provider's mid-risk plan is therefore already more diversified than two equity-heavy plans held across providers, at one set of fees, not two. The upshot, reinforcing Sections 2 and 5: Diversify by lowering your risk level within one provider, not by adding a second.

4. One provider or both: The cost

Fees split into two kinds, and only one bears on the *split* decision:

- **Proportional fees** (a percentage of assets under management). If both providers charge the same rate they are *split-neutral*: A rate p on the whole pot costs the same whether it sits in one plan or two ($pW = pW_1 + pW_2$). Equal proportional fees therefore drop out of the one-vs-two decision entirely.
- **Flat fees** (a fixed kr/year administration charge, independent of balance). These are paid *per provider*, so a second provider adds its flat fee F_2 every year, however little you place there.

The split decision thus turns on flat fees – weighed against the diversification benefit – and, separately, on any *difference* in proportional rates between providers. Holding both providers instead of one costs the flat fee of the one you would otherwise drop: kr 984 a year for Velliv and kr 807 for PFA. Both values of F_2 are carried through below.

Is the diversification worth a second flat fee?

Express the diversification benefit the way it actually accrues, as a boost to the **compound** growth rate: The variance drain it removes, $\Delta g = (\sigma^2_{\text{single}} - \sigma^2_{\text{split}})/2$, where σ^2_{single} is the average variance of the two single plans. The diagnostic report derives this variance drain, and the certainty equivalent used later in this section, from the return moments.

For a cross-provider same-risk split this is **0.9 basis points per year** – the entire "gain that compounds" from holding two providers. In kroner it is $\Delta g \cdot W$, while the flat fee F_2 is paid every year regardless of W. The split pays only above a break-even balance $W^* = F_2/\Delta g$:

Table 7: Balance above which the cross-provider diversification covers a second provider's flat fee. The rows marked with a provider are its flat fee.

flat fee per year (kr)	break-even balance (kr)
404	4,564,000
807 (PFA)	9,116,000
984 (Velliv)	11,116,000
1,968	22,232,000

With PFA as the second provider, the diversification covers its flat fee only above a balance of about kr 9,116,000. With Velliv it takes about kr 11,116,000. Your balance of kr 1,000,000 is below both, so on pure diversification grounds one provider is enough. The benefit is only about 0.9 basis points a year, and the flat fee is paid in every low-balance year on the way up besides. A risk-averse investor values the volatility cut at γ times the variance drain in the mean-variance view, which divides the threshold by γ. At your risk aversion of 2 it falls to about kr 4,558,000 to kr 5,558,000, still above your balance.

How much cheaper must a second provider be?

The other reason to add a provider is that it is *cheaper proportionally*. Moving an amount W_2 to a provider whose rate is Δp lower saves $\Delta p \cdot W_2$ per year, which must cover its flat fee F_2. So a second provider must undercut the first by at least

$$\Delta p \;\geq\; \frac{F_2}{W_2}.$$

Table 8: Proportional-rate discount a second provider must offer to justify its flat fee, by amount placed there (W_2).

	kr 250,000	kr 500,000	kr 750,000	kr 1,000,000
F_2 = kr 807 (PFA)	0.32%	0.16%	0.11%	0.08%
F_2 = kr 984 (Velliv)	0.39%	0.20%	0.13%	0.10%
F_2 = kr 1,968	0.79%	0.39%	0.26%	0.20%

At your balance of kr 1,000,000, a second provider must be at least **0.08 to 0.10 percentage points/year** cheaper to break even on fees, the first figure for PFA's flat fee and the second for Velliv's. The diversification credit $\Delta g \cdot W$, about kr 89 a year at your balance, could be added to the left-hand side. It barely moves the bar. If a second provider is *strictly* cheaper on both fee types, the question is not whether to *add* it but whether to *switch* entirely.

The benefit the variance drain misses: Hedging an unidentifiable provider difference

The variance drain above compares the mix to the *average* single plan, treating the two providers' expected returns as known and equal. But the real risk in the provider choice is not knowing *which provider's drift will compound higher* – and that difference is precisely what the data cannot pin down.

Over the sample PFA-high out-returned Velliv-high by **1.2 percentage points a year**, with a standard error of 0.7 pp/yr (t = 1.7), so it is **not distinguishable from zero**. You could not have known in advance which would win. The diagnostic report's Sharpe section carries the reference-period version of this comparison and a plot of the two paths.

How much of that realised edge is chance? The data cannot pin down the tail, so we assume one: A skewed-t with $\nu = 3.5$ and $\xi = 0.7$, set in the inputs. Simulating two providers with the data's volatilities and correlation but *no* true difference in mean, the gap between them over the sample has its own spread purely from chance and fat tails.

Under this fat-tailed null, a gap at least as large as the realised one arises by chance about **13%** of the time, against 9% under normal theory. The fatter tail makes the realised lead even less surprising than normal theory implies. Either way the realised lead is well within what no edge at all produces, so it is not signal.

Committing to one provider is thus a bet on a difference in expected return that the data cannot identify: The relative drift is not distinguishable from zero, so there is no statistical basis for predicting which provider will compound higher. The stakes grow with the horizon – increasingly from the *estimation* uncertainty in the drift (which accumulates linearly) rather than path noise (which accumulates only as √horizon):

Table 9: Dispersion between the two providers' cumulative outcomes by horizon, vs the second provider's flat fee over the horizon (PFA's the lower figure, Velliv's the higher).

horizon	provider gap (1-sd)	share from estimation	gap on kr 1,000,000	flat fee over horizon
5 yr	7%	27%	72,205	4,035 to 4,920
10 yr	12%	43%	117,591	8,070 to 9,840
20 yr	21%	60%	206,617	16,140 to 19,680
30 yr	30%	69%	299,789	24,210 to 29,520

The **provider gap (1-sd)** column is one standard deviation of the spread between the two providers' cumulative outcomes at that horizon, the typical distance by which one ends ahead of the other. The **share from estimation** column is how much of that spread comes from not knowing the relative drift (which grows with the horizon), as opposed to ordinary path noise.

In kroner the gap dwarfs the flat fee. But the gap is symmetric, since you might land on either side, so what justifies hedging is its **risk-adjusted** value, not its raw size. For a saver with constant relative risk aversion γ, the certainty-equivalent value of holding both, agnostic about which is better, is about $\gamma\,\sigma^2_{\text{gap}}/8$, the result derived in the diagnostic report. Here σ^2_{gap} is the variance of the cumulative provider gap, combining path noise with the estimation uncertainty in the relative drift:

Table 10: Certainty-equivalent value (kr, on kr 1,000,000) of holding both providers instead of one, by relative risk aversion (RRA, columns). Compare with the flat fees, kr 807/yr (PFA) and kr 984/yr (Velliv): kr 8,070 to 9,840 over 10 yr, kr 16,140 to 19,680 over 20 yr.

	RRA 1	RRA 2	RRA 4
10 yr	1,545	3,090	6,180
20 yr	4,410	8,819	17,638

At your risk aversion of 2 and a 20-year horizon, the certainty-equivalent value of holding both providers is about kr 8,819, against kr 16,140 to kr 19,680 of extra flat fees over that horizon, depending on which provider is the second. So the hedge falls short of its cost either way, covering about 45% to 55% of it. The large realised gap is hindsight, not an expected gain. It would clear only for a more risk-averse saver or a longer horizon. The risk-level choice of Sections 2 and 5 remains the larger lever, and all of this assumes the saver does not chase the apparent drift edge that Section 2 says cannot be trusted.

The break-evens above read off the flat fees and the balance set in the Inputs section.

A second lens: The split as insurance

The certainty equivalent prices the body of the distribution. A complementary view, free of any distributional assumption, treats the split as insurance. A 50/50 buy-and-hold split ends at the average of the two single outcomes, so its terminal wealth always lands between the worse and the better provider. Splitting removes the risk of committing to the worse provider, and pays for it by giving up the better provider's upside.

Over the sample, 1 kr grew to about 3.9 kr in PFA-high and about 3.3 kr in Velliv-high. A 50/50 buy-and-hold split would have ended at about 3.6 kr, between the two. The premium is symmetric, and you cannot know in advance which provider will win, since the realised drift gap is not distinguishable from zero, as shown above.

The honest limit of this lens is that the insurance cannot be priced reliably against the flat fee. Its value depends on the dispersion of the provider gap, and under the heavy tails the returns reports document that dispersion is not something the data pin down. The Monte Carlo in Section 5, and the long-horizon simulations in the returns reports, show that compounded outcomes over a long horizon can diverge to an extreme degree. So the mean-variance certainty equivalent gives a point estimate that covers only 45% to 55% of the flat fees, while the insurance lens says the protection is real but its price is genuinely uncertain. The decision rests on how much an unquantifiable hedge against picking the worse provider is worth to the saver, set against a known annual flat fee.

5. Does a second provider help in the tail?

Sections 2–4 are second-moment – Sharpe, correlation, volatility. The returns reports show the second moment is the wrong lens: The tail index ν is around 3–5, returns are left-skewed, and correlation is itself unstable under fat tails. The decision-relevant question is whether holding two providers protects the *tail* – a crash – and by how much.

The data fix each plan's *marginal* (mean, volatility, fat-tailed shape) and the *linear correlation* between providers (about 0.97 for two high-risk plans), but they do **not** fix the *tail dependence*: Whether the two crash *together* (a systemic equity selloff) or whether one can crash *alone*. So rather than a single number we simulate three models that **all match the observed means, volatilities and correlation** and differ only in the tail – a **Gaussian** world (no fat tails); the fitted skewed-t marginals with **independent** crashes (a Gaussian copula); and the same marginals with **coincident** crashes (a Student-t copula). For each we compare holding one high-risk plan (100% Velliv high) against a 50/50 provider split (Velliv high + PFA

high) over **one year** – the horizon at which a crash actually bites (over twenty years the law of large numbers smooths the monthly tails away and the split's effect all but vanishes).

Table 11: One-year wealth (start = 100): One high-risk plan vs a 50/50 provider split, under three models matched on mean, volatility and correlation.

	single 5th-pct	single P(loss>10%)	split 5th-pct	split P(loss>10%)
Gaussian	90.09	4.89	91.86	3.14
Fat, independent crashes	89.90	5.10	91.75	3.72
Fat, coincident crashes	89.69	5.13	91.41	3.87

Three things stand out. **Fat tails make the single plan riskier than a Gaussian view admits.** The chance of a one-year loss worse than 10% rises from about 4.9% under the Gaussian to about 5.1% with fat tails, and for deeper losses the gap widens. **Splitting across two same-risk providers helps only modestly.** It trims that probability to about 3.7% and lifts the 5th-percentile floor by about 1.8 points. And crucially, **that modest benefit barely moves between the independent-crash and coincident-crash models**: At a correlation of 0.97 the bulk co-movement already caps the diversification, so the tail dependence we *cannot* estimate turns out not to change the answer. Provider-splitting at the same risk level is a weak crash hedge, since two highly-correlated providers mostly fall together.

The far larger lever for crash protection is the **risk level itself**: The bond sleeve of a lower-risk plan cuts the crash probability much more than a second provider does (the flip side of the "Path crossing" result in the returns reports – the lower-risk plan genuinely cushions a drawdown, at the cost of expected return). The one diversification a *returns* analysis cannot see is **provider-specific operational risk** – a fund or administrator failing on its own – which is the strongest remaining argument for splitting and lies outside this data.

6. Monitoring: What has changed?

These choices are not made once. The data that drive them – the regime, the gap between providers, what each plan holds, the fees – change, and a wrong assumption ("the bull market will continue") reveals itself only with time. This tool is therefore also meant to be **re-run periodically as a monitor**, flagging when a decision needs revisiting:

- **Regime shifts** – a change in the level of returns, in volatility, or in the tail that would alter the *risk-level* choice (e.g. when staying in a high-risk plan stops looking safe).
- **Provider divergence** – a widening gap between the providers' cumulative outcomes. Over 2012-07 to 2025-11, 1 m DKK in PFA-high grew to about 3.9 m versus about 3.3 m in Velliv-high, a spread of about 0.6 m, with PFA-high compounding about 1.2 pp/year faster. No one could have called this in advance. A monitor shows such a gap opening and forces the question of whether it is signal or luck.
- **Composition or fee changes** – e.g. PFA's restructuring of 1 April 2025, which renamed its profiles and moved B and C toward equities, or any change in the flat fees that drive the Section 4 arithmetic.

Distance to a path crossing

Section 2 showed the high plan is a leverage of the medium plan, and the diagnostic report shows the flip side: The high plan trails the medium plan exactly while the medium plan sits below its entry value. The distance to a crossing is therefore the cushion the medium plan has built above the chosen entry, and a crossing begins once a drawdown gives that cushion back. The table reads this off for each provider, from the saver's entry (the start of the supplied data by default) and from the medium plan's most recent peak.

Table 12: Distance to a within-provider path crossing. The high plan trails the medium plan once the medium plan falls back to its entry level. 'Drawdown to a crossing' is the fall from today, gradual or in a single month, that would trigger it; 'drawdown from peak now' is how far the medium plan already sits under its running high; 'medium return, 6m' shows whether the cushion is widening (positive) or narrowing.

provider	cushion since entry	drawdown to a crossing	drawdown from peak now	medium return, 6m
Velliv (high vs med)	+172%	63%	0%	+8.7%
PFA (D vs B)	+141%	59%	0%	+7.2%

What to read in the table. The **drawdown to a crossing** is how far the medium plan must fall from today before the high plan slips behind it. It is large from a long-held entry and small from a recent one, because the cushion is whatever the plan has gained since the entry. The **drawdown from peak now** is the fragile reading: An entry at the medium plan's most recent peak is closest to a crossing, since any further fall puts the plan below its entry. That is the situation the diagnostic report illustrates with the COVID-eve example. A positive six-month medium return means the cushion is widening and a crossing receding; a negative one means it is narrowing. This is the within-provider crossing, the high plan against its own medium plan, separate from the cross-provider spread above.

Has the return structure changed?

The tool monitors *structure*, not only level. The bluntest signal is the number of return streams: When a provider splits or merges its profiles, the column count changes. A reweighting leaves the count intact. PFA's April 2025 restructuring is an example: Its feed kept all four profiles under new names, but two of them took on more equity. Such subtler shifts, and a change of underlying funds, show up as drift in the per-provider leverage, the volatility of the lower-risk plans, and the correlations. The check below compares a baseline window with the most recent months.

Table 13: Structure check: Baseline window vs the most recent 36 months. The data carry 7 return streams; a change in that count is itself an obvious structural change.

metric	baseline	recent	change
Velliv leverage β (high on med)	1.26	1.28	+0.01
PFA leverage β (high on med)	1.59	1.63	+0.04
Velliv medium volatility (ann.)	8.5%	7.1%	-1.4 pp
PFA medium volatility (ann.)	6.0%	5.4%	-0.6 pp
Velliv low-high correlation	0.99	0.98	-0.00
PFA low-high correlation	0.90	0.92	+0.02

These drifts mix market conditions with policy. PFA's profiles allow a sharper test, because each is a fixed blend of the two funds of Section 3, $H = D$ and $L = (4A - D)/3$. A profile's share in the high-risk fund changes only when PFA reweights it, whatever the market does. The scan below finds, for B and C, the month that best splits the window into two constant shares.

Table 14: Reweighting scan for PFA's middle profiles: The share of the high-risk fund before and after the best single split of the window, and how much of a constant-share fit's misfit that split removes.

profile	best split	high-risk share before	high-risk share after	misfit removed
PFA B	2025-04	50%	60%	94%
PFA C	2025-04	75%	95%	98%

The scan flags a reweighting: From 2025-04, PFA B moved from 50% to 60% and PFA C moved from 75% to 95% high-risk fund. That is a change of policy, not of market conditions. Only the last 8 months carry the new weights, so the full-window figures above still mostly describe the old profiles. Going forward, judge these profiles by their new weights, not by their history. A flag is a prompt to ask which of three causes is at work, market conditions, a change of policy, or a change in the underlying funds and weights, and then to revisit the risk-level and provider decisions above.

7. Verdict

On the loaded data and your inputs:

- **Risk level.** Velliv reads as a leverage ray, and PFA's profiles also read as a ray within the noise. In both, pick the risk level by drawdown tolerance; there is nothing to optimise. The larger lever, for growth and for crash protection alike, is the risk level itself, not the provider. PFA reweighted B and C from 2025-04, so choose among its profiles by their new weights.
- **One provider or both.** The best cross-provider mix (PFA A + Velliv high) cuts volatility about 2.5%. On diversification grounds one provider is enough at your balance. As insurance against the unidentifiable provider difference, the certainty equivalent (kr 8,819) falls short of the extra flat fees over your horizon (kr 16,140 to kr 19,680), and the joint simulation makes a same-risk split a weak crash hedge. The strongest case for a second provider is operational risk, which the return data cannot measure.
- **Trust.** The loaded data are heavy-tailed, and the tail is not pinned down at 161 months. Treat every figure here as direction, not precision, and re-run the tool as the data grow.
